**Abstract.** *In the analysis of ship structures at small scale, with structural details heterogeneities and because there is only one prototype produced, which is the final product, the designers rely on finite element simulations. The finite element discretization of such structure, leads to a huge global numerical model, that suffers for computational cost and memory resource that may be unaffordable. In such a case, a multi-scale analysis should be performed. The classical local-global analysis that is used by engineers has several limitations such as:*

- *structure details are not periodic, therefore classical homogenization methods are not easily applicable;*
- *edge effects are not take into account;*
- *zooming techniques are not easy to use: the gluing they require with the global scale often introduces artificial edge effects.*

*This paper presents a micro-macro strategy based on the domain decomposition FETI-DP method as the solver in analysis of ship structure. With this approach, the two scales (micro and macro) are coupled during the iterations of the solver and we can consider the structural details in areas of interest, area where the fine mesh is used and a sub-domain is located. Performances are discussed and results in term of convergence are presented for several examples.*

## 1 INTRODUCTION

Analysis of a large system like ship structure, to obtain the fine scale results is one of the industrial challenges today. Since there is often only one prototype produced, which is the final product and because real-scale test of such structures are very expensive and difficult, the designers now often rely on finite element simulation. Due to the classification society rules and regulations, extensive use of numerical simulations started only recently in this domain of engineering. With the advent of new design for ships, the old rules and regulations were obsolete and engineers shifted to the numerical simulation and in particular to the finite element method. Due to different specifications, several discretized models are used:

- for global behavior of the structure, and regulations requirements of numerical tests, a so called coarse finite element model is used, see Figure 1;
- for local stresses, and to take into account all details (skylight, doors, ...) a model at a finer scale is required;
- for vibration analysis, ...;
- for fatigue life assessment, ...;

Figure 1: Global finite element model

To obtain a solution for the whole structure as well as a local solution near the details, a small scale discretized model is required. This would lead to a huge global finite element model with large number of unknowns that is very expensive to solve. Because of this large number of unknowns, memory and processors limits, computing this kind of problem with a classical direct technique is not feasible at the moment, even with last generation sparse solvers. Therefore, using a simplified global model is mandatory and engineers have used approximate method based on super-element or local-global analysis.

Briefly, the local-global methods, which are used in engineering consist of several steps:

- Solving a local or microscopic problem to derive its global behavior for very parts of the structure;
- Construction of a global or macroscopic model of the ship with an equivalent homogenized constitutive behavior by the results of the first step;
- Once the global model is solved, recovering the solution on the small scale of the details with a post-processing step.

The use of such a strategy raises several difficulties:

First, we can not use the periodic homogenization approach, since the structural details are not periodic. So we need the appropriate assumptions on boundary conditions for the local problems dealing with structural details.

Second, the same boundary conditions are used for the post-processing re-localization phase,

needed to recover the small scale solution. Depending on the selected boundary conditions, artificial edge effects may appear that pollutes the local stress computations. These edge effects, as well as approximations in the homogenized behavior, are the consequence of loosely coupled global and local computations.

To overcome to the above mentioned drawbacks, we will use domain decomposition methods that will allow to restore the coupling between the different scales along iterations. Numerous domain decomposition methods are discussed in the literature. They differ in the way gluing conditions are expressed between neighboring substructures.

Another difficulty lies in the fact that complex structures as ships are assemblies of different structural elements like shells, joints and stiffeners. Usually the stiffeners are modeled with beam finite elements while various panels uses shell or plate finite element and joints use special transition elements.

Therefore, we propose to use a domain decomposition approach suited to:

- couple local fine scale models of predefined areas (or sub-domain);
- glue these local models to areas without zooming, i.e, with a coarse finite element model;
- provide a mechanism to homogenize fine scale sub-domains to coarse finite elements;
- deal with previously mentioned heterogeneities.

In this article, we will not tackle the problem of gluing local models to coarse models. We propose to use the dual-primal version of the FETI method, which is briefly described in Section 2. The same Section recalls the technology used in such methods to deal with classical heterogeneities.

The Section 3 presents the problem of interface in the case of the 3D mesh of the ship structure and different heterogeneity in this structure. We will present the results of the two simple problems and a real 3D problem of a slice of the ship structure in Section 4. The results and conclusion will be in the Section 5.

## 2 GENERAL DESCRIPTION OF THE FETI-DP METHOD

Domain decomposition methods are both an efficient and flexible tool for structural analysis [6],[4]. As an iterative approach, they often outperform direct methods when the size of the model increases, and they allow a parallel treatment of the resolution phase. In this article, we are not concerned with the parallelization of the resolution, but we focuss on the modularity, especially for coupling different areas (different sub-domains) that may have been modeled differently, or with different discretization levels.

To reach numerically scalability, the domain decomposition method needs a multi-scale feature, mainly to be able to built a coarse problem that maintains the convergence rate weakly dependent on the number of substructures, among these methods, one can refer to BDD [7], CBDD [8], aggregation technique [10], [9], FETI [3], FETI-DP [2], [1], LATIN micro-Macro [5]. Moreover, when this coarse problem is related to an homogenized model of the same structure, this provides an efficient tool to deal with heterogeneous structures.

The different versions of the FETI method (FETI-1 [3], FETI-2, FETI-DP [2], [4], ...) belongs to the family of the non overlapping domain decomposition methods with lagrange multiplier.

These methods have been developed for solutions of the large scale systems of equations in structural analysis by finite element method. Among all the domain decomposition methods that were presented by many others author, we choose the FETI-DP method for the following reasons:

Usually with a multi-scale domain decomposition method, the reference problem is split into sub-domains and the coarse space problem is numerically built from this fine scale description. The coarse problem can be discrete by nature, and is not always related to any finite element model.

In the case we are interested in, the coarse problem is already provided, and the reference problem is built from this coarse problem by selecting zooming area that are coarse finite elements (a panel or a stiffener, for instance). A selected coarse finite element is re-meshed at a fine scale with the corresponding structural details (skylight, door, ...) and is identified as a sub-domain. The initial coarse finite element possesses nodes that are suitable to be chosen as corner nodes of the FETI-DP method.

Moreover, as detailed in the following (see Figure 2), the coarse finite element model constitutes a structural homogenization of the detailed sub-structures, and the compatibility of coarse displacement field is ensured automatically with neighboring coarse elements.

Figure 2: Coarse finite element model and a fine scale sub-domain

## 2.1 Basic FETI-DP method

Let us consider the domain  $\Omega$ , decomposed that into  $N$  non-overlapping sub-domains (or substructures)  $\Omega^s$ . Let  $K^s$ ,  $u^s$  and  $f^s$  be the stiffness matrix, displacement and prescribed force vectors associated with sub-domain of  $\Omega^s$ , respectively. By splitting  $u^s$  into corner and reminder points we will have:

$$u = \begin{bmatrix} u_r \\ u_c \end{bmatrix} = \begin{bmatrix} u_r^1 \\ \vdots \\ u_r^{N_s} \\ u_c \end{bmatrix} \quad (1)$$

Where  $u_c$  is the global or primal solution vector of the corners degrees of freedoms (d.o.f) and  $u_r^s$  is solution vector of the remaining sub-domains degrees of freedoms. With this kinematic description, the solution at corner point is globally continuous. Using this notation, we can split the sub-domain stiffness matrix into:

$$K^s = \begin{bmatrix} K_{rr}^s & K_{rc}^s \\ K_{rc}^{sT} & K_{cc}^s \end{bmatrix} \quad (2)$$

By writing the equilibrium equation for each sub-domain in the global form and considering the continuous boundary condition on the interface of the sub-domains we will have the following relations:

$$K_{rr}^s u_r^s + K_{rc}^s B_c^s u_c + B_r^{sT} \lambda = f_r^s \quad \text{for all } s=1, \dots, N_s \quad (3)$$

$$\sum_{s=1}^{s=N_s} B_c^{sT} K_{rc}^{sT} u_r^s + \sum_{s=1}^{s=N_s} B_c^{sT} K_{cc}^s B_c^s u_c = \sum_{s=1}^{s=N_s} B_c^{sT} f_c^s = f_c \quad (4)$$

Where  $B_c^s$  are boolean matrices that map the local corner d.o.fs of a sub-domain to the global corner d.o.fs:

$$u_c^s = B_c^s u_c \quad (5)$$

The interface continuity condition can be written as follows:

$$\sum_{s=1}^{s=N_s} B_r^s u_r^s = 0 \quad (6)$$

where  $B_r^s$  are signed boolean matrices.

With the above equations and after some algebraic transformations, we obtain the following dual-primal problem. with Lagrange multiplier  $\lambda$  and primal displacement  $u_c$  as unknowns.

$$\begin{bmatrix} F_{I_{rr}} & F_{I_{rc}} \\ F_{I_{rc}^T} & -K_{cc}^* \end{bmatrix} \begin{bmatrix} \lambda \\ u_c \end{bmatrix} = \begin{bmatrix} d_r \\ -f_c^* \end{bmatrix} \quad (7)$$

where:

$$F_{I_{rr}} = \sum_{s=1}^{s=N_s} B_r^s K_{rr}^{s-1} B_r^{sT} \quad (8)$$

$$F_{I_{rc}} = \sum_{s=1}^{s=N_s} B_r^s K_{rr}^{s-1} K_{rc}^s B_c^s \quad (9)$$

$$K_{cc}^* = K_{cc} - \sum_{s=1}^{s=N_s} (K_{rc}^s B_r^s)^T K_{rr}^{s-1} (K_{rc}^s B_c^s) \quad (10)$$

$$d_r = \sum_{s=1}^{s=N_s} B_r^s K_{rr}^{s-1} f_r^s f_c^* = f_c - \sum_{s=1}^{s=N_s} B_c^{sT} K_{rc}^{sT} K_{rr}^{s-1} f_r^s \quad (11)$$

The symmetric positive definite dual interface problem is obtained by condensing the  $u_c$  on the  $\lambda$ :

$$(F_{I_{rr}} + F_{I_{rc}} K_{cc}^{*-1} F_{I_{rc}}^T) \lambda = d_r - F_{I_{rc}} K_{cc}^{*-1} f_c^* \quad (12)$$

We use the preconditioning conjugate gradient algorithm (PGC), as a solver of the above interface problem. Indeed because the number of unknowns in the above equation can be large and because computing and assembling that for each substructure would be very expensive, (2.1) is not solved by a direct method.

The kernel of the equation (2.1) is the computation of the coarse FETI-DP matrix  $K_{cc}^*$ . The matrix  $K_{cc}^*$  is sparse and its pattern is that of a stiffness matrix obtained by considering only the super-elements defined by the corner nodes.

## 2.2 Preconditioning for heterogeneous problems

Like all iterative methods, FETI-DP solver performances depend on spectral properties of the matrix of the linear system and demand a good conditioning of the equations. In this article, we do not develop a new preconditioner for FETI-DP method. The preconditioner [4] are:

$$\bar{F}_{I_{rr}}^{D-1} = \sum_{s=1}^{s=N_s} W^s B_r^s \begin{bmatrix} 0 & 0 \\ 0 & S_{b_r b_r}^s \end{bmatrix} B_r^{sT} W^s \quad (13)$$

where, for the Dirichlet preconditioner :

$$S_{b_r b_r}^s = K_{b_r b_r}^s - K_{ib_r}^{sT} K_{ii}^{s-1} K_{ib_r}^s \quad (14)$$

and for the Lumped preconditioner:

$$S_{b_r b_r}^s = K_{b_r b_r}^s \quad (15)$$

$W^s$  is a scaling diagonal matrix for the heterogeneous cases and  $i$ ,  $b$  and  $r$  are internal nodes, boundary nodes and total internal and boundary nodes, respectively.

For more informations the reader can refer to [3], [2], [1].

## 3 INTERFACE PROBLEM IN THE CASE OF SHIP STRUCTURES

The ship structure is assemblage of the very different structural elements such as shell, plate, stiffeners, joints, etc. We consider stiffeners in two categories, primary and secondary stiffeners. All secondary stiffeners is considered into the plate sub-domain and all primary are consider like the one sub-domain. As a rule we decompose the structure in the line of intersection of the all plate and primary stiffeners. For this reason in interface line there are three lagrange multiplier. We applied the DKQ element (with 6 d.o.fs  $u$ ,  $v$ ,  $w$ ,  $\theta_x$ ,  $\theta_y$ ,  $\theta_z$  at each node) and 2 node beam element (with 6 d.o.fs  $u$ ,  $v$ ,  $w$ ,  $\theta_x$ ,  $\theta_y$ ,  $\theta_z$  at each node).

## 4 NUMERICAL EXAMPLES

For illustration of the performance of the above mentioned method we present two examples. The problem is a model problem of a 2D stiffened plate and is used to test the convergence of the method. The second problem concerns a 3D analysis of a slice of a ship with a fine finite element model.

### 4.1 2D stiffened plate

We consider herein the 2D static deflection and plane stress analysis of a plate with (problem I) or without (problem II) stiffeners. Both are related to a rectangular domain, clamped on the bottom side.

We use DKT elements (three node triangular plane stress elements with two d.o.fs at each node) made with steel (young's modulus  $E = 2.0 \times 10^{11} \text{ N/m}^2$  and Poisson's ratio  $\nu = 0.3$ )

For problem II, an assembling of plates and stiffeners is considered. The stiffeners are discretized with two node beam elements (three d.o.f for each node, two displacements,  $u$  and  $v$ , and rotation  $\theta$ ). The material characteristics of the stiffeners are Young's modulus  $E = 2.0 \times 10^{11} \text{ N/m}^2$ , Poisson's ratio  $\nu = 0.3$ , cross section area  $S = 0.00295 \text{ m}^2$  and section moment of inertia to  $I = 1.4471 \times 10^{-6} \text{ m}^4$  for bending.

We suppose that the stiffeners lie on the interfaces of the decomposition into sub-domain. We prescribe an uniform shear force on the top side of the two above problems (see Figure 3).

The results of the above mentioned problems with different sub-domain sizes  $H$  and delement

Figure 3: Plane stress problem

sizes  $h$  with application of the FETI-DP solver and Dirichlet preconditioner are shown in Figures 4 and 5.

The rate of convergence is still higher for the problem without stiffeners, even when using the Dirichlet preconditioner. With diagonal scaling and three lagrange multipliers this behavior is still to be studied to recover the initial convergence rate.

Figure 4: Convergence behavior (plate without stiffener)

## 4.2 A 3D analysis of a slice of ship

In order to tackle a more realistic problem, we consider a slice of the passenger ship as shown in Figure 2. Pre and post processing is performed with the FE code Cast3M (CEA sacly, France) and reduction is achieved in a prototype FE platform in Matlab environment. The finite element characteristic of this structural model as shown in Table 4.2:

Item	No.
Length, Breadth, Depth	11.6 m, 9.43 m, 22.1 m
Number of fine mesh nodes	11082
Number of element	11065
Number of d.o.fs	66492
Number of sub-domain (mesh coarse)	237

Table 1: Characteristic of the slice of the ship.

## 5 CONCLUSIONS

In this paper we was succeed to use domain decomposition method and FETI-DP method such as solver in the static analysis of the ship structure. We considered one coarse mesh that the fine mesh (structural details) is hidden behind that and also we consider all primaries stiffeners in one sub-domain.

The obtained results is comparable of the CAST3M finite elements code. A Matlab code is

Figure 5: Convergence behavior (plate with stiffener)

developed for this reason and it will be continued to decrease the rate of the convergence and applicable of the method in the free vibrational analysis.
